Robust real-time tracking by fusing measurements from inertial and vision sensors

Received: date / Revised: date

Abstract The problem of estimating and predicting position and orientation (pose) of a camera is approached by fusing measurements from inertial sensors (accelerometers and rate gyroscopes) and vision. The sensor fusion approach described in this contribution is based on non-linear filtering of these complementary sensors. This way, accurate and robust pose estimates are available for the primary purpose of augmented reality applications, but with the secondary effect of reducing computation time and improving the performance in vision processing.

A real-time implementation of a multi-rate extended Kalman filter is described, using a dynamic model with 22 states, where 100 Hz inertial measurements and 12.5 Hz correspondences from vision are processed. An example where an industrial robot is used to move the sensor unit is presented. The advantage with this configuration is that it provides ground truth for the pose, allowing for objective performance evaluation. The results show that we obtain an absolute accuracy of 2 cm in position and 1° in orientation.

1 Introduction

This paper deals with estimating the position and orientation (pose) of a camera in real-time, using measurements from inertial sensors (accelerometers and rate gyroscopes) and a camera. A system has been developed to solve this problem in unprepared environments, assuming that a map or scene model is available. For a more detailed description of the overall system and the construction of scene models we refer to Stricker and Thomas (2007) and Koeser et al (2007), respectively. In this paper, the sensor fusion part of the system is described, which is based upon a rather general framework for nonlinear state estimation available from the statistical signal processing community.

This problem can under ideal conditions be solved using only a camera. Hence, it might seem superfluous to introduce inertial sensors. However, the most important reasons justifying an *inertial measurement unit* (IMU) are:

- Producing more *robust* estimates. Any single camera system will experience problems during periods with uninformative or no vision data. This will occur, typically due to occlusion or fast motion. An IMU will help to bridge such gaps, which will be illustrated in the present paper.
- Reducing computational demands for image processing. Accurate short time pose estimates are available using the information from the IMU, reducing the need for fast vision updates.

The combination of vision and inertial sensors has been used previously in literature. Corke et al (2007) give an introduction to this field and its applications. Reported systems apply various methods: inertial measurements are used as backup (Aron et al 2007), for short time pose prediction (Klein and Drummond 2004), or depth map alignment (Lobo and Dias 2004). Alternatively, vision and inertial subsystems are loosely coupled, using visual pose measurements (Ribo et al 2004; Chroust and Vincze 2004; Armesto et al 2007). Vision relies on either specific targets, line contours or natural landmarks. Calibration of the sensors is discussed in e.g., (Lobo and Dias 2007). Furthermore, the problem is closely related to the problem of *simultaneous localization and mapping* (SLAM) (Durrant-Whyte and Bailey 2006; Thrun et al 2005),

where camera tracking and scene model construction are performed simultaneously. Single camera SLAM is discussed in Davison (2003); Davison et al (2007). In that context so called fast localization algorithms (Williams et al 2007) are investigated as alternatives to inertial support (Pinies et al 2007; Gemeiner et al 2007).

In our approach, real-time camera pose estimation is achieved by fusing inertial and vision measurements using the framework of nonlinear state estimation, covering methods such as the *Extended Kalman Filter* (EKF), the *Unscented Kalman Filters* (UKF) and the *particle filter* (PF). This results in a tightly coupled system, naturally supporting multi-rate signals. The vision measurements are based on natural landmarks, which are detected guided by pose predictions. The measurements from the sensors are used directly rather than being processed to a vision based pose or an inertial based pose. The components of the system are well known. However, we believe that the way in which these components are assembled is novel and we show that the resulting system provides accurate and robust pose estimates.

The sensors generating the measurements y_t are described in Section 2. In Section 3, the framework for state estimation in nonlinear dynamic systems is introduced in more detail and used to solve the sensor fusion problem we are faced with in the present application. In implementing this, there are several practical issues that have to be solved. The overall performance of the system heavily relies on successful solutions to these matters, which is explained in Section 4. The performance of the implementation is evaluated in Section 5, and finally, the paper is concluded in Section 6.

Fig. 1 A prototype of the MATRIS project, integrating a camera and an IMU in a single housing. It provides a hardware synchronized stream of video and inertial data.

2 Sensors

An IMU and a digital video camera are combined to provide measurements to the sensor fusion module, described in this paper. Both sensors are relatively small and unobtrusive and they can be conveniently integrated into a single *sensor unit*. An example of a prototype is shown in Figure 1. An on board digital signal processor containing calibration parameters is used to calibrate and synchronize data from the different components.

Before discussing the inertial and vision sensors in the subsequent sections, the required coordinate systems are introduced.

2.1 Coordinate systems

When working with a sensor unit containing a camera and an IMU several coordinate systems have to be introduced:

- **Earth (e)**: The camera pose is estimated with respect to this coordinate system. It is fixed to earth and the features of the scene are modelled in this coordinate system. It can be aligned in any way, however, preferably it should be vertically aligned.
- **Camera (c)**: The coordinate system attached to the moving camera. Its origin is located in the optical center of the camera, with the z-axis pointing along the optical axis. The camera, a projective device, acquires its images in the **image plane (i)**. This plane is perpendicular to the optical axis and is located at an offset (focal length) from the optical center of the camera.
- **Body (b)**: This is the coordinate system of the IMU. Even though the camera and the IMU are rigidly attached to each other and contained within a single package, the body coordinate system does not coincide with the camera coordinate system. They are separated by a constant translation and rotation.

These coordinate systems are used to denote geometric quantities, for instance, $\boldsymbol{c}^e$ is the position of the camera coordinate system expressed in the earth system and R^{cb} is the rotation matrix from the body system to the camera system.

2.2 Inertial sensors

The sensor unit contains an IMU with three perpendicularly mounted 1200 degree/s ADXLXRS300 angular velocity sensors and two 5g 2D ADXL22293 accelerometers, which are mounted such that three of the sensitive axes are perpendicular to each other. MEMS rate gyroscopes are chosen because of their dramatically reduced size and low cost as compared to alternatives such as fiber optic angular velocity sensors.

The signals from the inertial components are synchronously measured at 100 Hz using a 16 bit A/D converter. A temperature sensor is added to compensate

for the temperature dependency of the different sensing components.

The assembly containing the gyroscopes and accelerometers has been subjected to a calibration procedure to calibrate for the exact physical alignment of each component, the gains, the offsets and the temperature relations of the gains and offsets. With these a 3D angular velocity vector and a 3D accelerometer vector, both resolved in the body coordinate system, are computed using an on board processor. See e.g., Titterton and Weston (1997); Chatfield (1997) for suitable background material on inertial sensors and the associated signal processing.

The calibrated gyroscope signal $\boldsymbol{y}_{\omega,t}$ contains measurements of the angular velocity $\boldsymbol{\omega}^b_{eb,t}$ from body to earth ($_{eb}$) expressed in the body coordinate system (^{b}):

$$\boldsymbol{y}_{\omega,t} = \boldsymbol{\omega}^b_{eb,t} + \boldsymbol{\delta}^b_{\omega,t} + \boldsymbol{e}^b_{\omega,t}. \tag{1}$$

Even though the gyroscope signal is corrected for temperature effects, some low-frequency offset fluctuations $\boldsymbol{\delta}_{\omega,t}$ remain, partly due to the unmodeled acceleration dependency. The remaining error $\boldsymbol{e}^b_{\omega,t}$ is assumed to be zero mean white noise. The measurements are not accurate enough to pick up the rotation of the earth. This implies that the earth coordinate system can be considered to be an inertial frame.

A change in orientation can be obtained by proper integration of the gyroscope signal. This orientation can be obtained even during fast and abrupt movements, not relying on any infrastructure other than the gyroscope itself. However, the accuracy in orientation will deteriorate for periods longer than a few seconds.

The calibrated accelerometer signal $\boldsymbol{y}_{a,t}$ contains measurements of the combination of the body acceleration vector $\ddot{\boldsymbol{b}}_t$ and the gravity vector $\boldsymbol{g}$, both expressed in the body coordinate system:

$$\boldsymbol{y}_{a,t} = \ddot{\boldsymbol{b}}^b_t - \boldsymbol{g}^b + \boldsymbol{\delta}^b_{a,t} + \boldsymbol{e}^b_{a,t}. \tag{2}$$

Even though the accelerometer measurement is corrected for temperature effects a small low-frequency offset $\boldsymbol{\delta}_{a,t}$ remains. The error $\boldsymbol{e}^b_{a,t}$ is assumed to be zero mean white noise.

Gravity is a constant vector in the earth coordinate system. However, expressed in body coordinates gravity depends on the orientation of the sensor unit. This means that once the orientation is known, the accelerometer signal can be used to estimate the acceleration, or alternatively, once the acceleration is known, the direction of the vertical can be estimated.

Accelerations can be integrated twice to obtain a change in position. This can be done during fast and abrupt motions as long as an accurate orientation estimate is available, for instance from the gyroscopes. However, the accuracy of the position change will deteriorate quickly as a result of the double integration and the sensitivity with respect to orientation errors.

2.3 Monocular vision

Apart from the inertial sensors, the sensor unit is equipped with a ptGrey DragonFly CCD camera with a perspective lens with a focal length of 3.2 mm. Color images with a resolution of 320x240 pixels at a frame rate of 12.5 Hz are streamed to a PC using a firewire connection. The camera is triggered by the IMU clock allowing for synchronized measurements.

This setup is one realization of monocular vision: cameras can vary in sensor type, resolution, frame rate and various lens types can be used, ranging from perspective to fish-eye. However, they remain projective devices, that is, they are bearings only sensors which do not provide distance directly.

Extracting camera position and orientation from images is a known and well studied problem in computer vision (Ma et al 2006; Hartley and Zisserman 2004). The key ingredient is to find correspondences, relations between a feature found in the image which corresponds to an element in the scene model. All these are rather abstract concepts, which do have numerous implementations, ranging from Harris detectors (Harris and Stephens 1988) and point clouds models to patches and textured free-form surfaces models (Koeser et al 2007). The correspondences are the pieces of information which can be extracted from an image and they will be considered to be the vision measurements in this article.

Point correspondences $\boldsymbol{z}^c \leftrightarrow \boldsymbol{z}^i$ are the relation between 3D points $\boldsymbol{z}^c$ and 2D image points $\boldsymbol{z}^i$. For a perspective lens and a pinhole camera the correspondence relation is

$$\boldsymbol{z}^i = \begin{pmatrix} f z^c_x / z^c_z \\ f z^c_y / z^c_z \end{pmatrix} + \boldsymbol{e}^i, \tag{3a}$$

or equivalently,

$$\boldsymbol{0} \approx \begin{pmatrix} -f I_2 & \boldsymbol{z}^i_t \end{pmatrix} \boldsymbol{z}^c_t = \begin{pmatrix} -f I_2 & \boldsymbol{z}^i_t \end{pmatrix} R^{ce}_t (\boldsymbol{z}^e - \boldsymbol{c}^e_t), \tag{3b}$$

where f is the focal length and I_2 the 2×2 identity matrix. The error $\boldsymbol{e}^i_t$ is assumed to be a zero mean white noise. Here it is worth noting that this assumption is not that realistic, due to outliers, quantization effects etc. From (3b) it can be seen that the camera pose depends on the rotation matrix R^{ce} and the position $\boldsymbol{c}^e$. Hence, given sufficient correspondences and a calibrated camera the camera pose can be solved for. Similar relations can be derived for e.g., line correspondences which also provide information about the camera pose and optical velocity fields which provide information about the camera velocity (Corke et al 2007).

Correspondences are bearings only measurements and as such they provide information about absolute position and orientation with respect to the earth coordinate system. Note that everything is determined up to a scale ambiguity; viewing a twice as large scene from double distance will yield an identical image. However, these vision measurements are available at a relatively low rate

due to the trade off between exposure time and accuracy (pixel noise and motion blur) which is an important limit for small aperture cameras. Furthermore, processing capacity might constrain the frame rate. Hence, the observed image can change drastically from frame to frame, which occurs already with normal human motion. This is the main cause for the limited robustness inherent in single camera systems.

The computer vision implementation used in the present implementation is based on a *sum of absolute difference* (SAD) block matcher in combination with a planar patch or free-form surface model of the scene. More details can be found in Stricker and Thomas (2007); Koeser et al (2007); Skoglund and Felsberg (2007). Both pixel data and 3D positions are stored for each feature. An example of a scene model is shown in Figure 2. While

Fig. 2 An example of a scene model consisting of planar patches (*lower right*) and the actual scene that is modelled (*upper left*).

tracking, search templates are generated by warping the patches in the model according to homographies calculated from the latest prediction of the camera pose. These templates are then matched with the current calibrated camera image using the block matcher. In this way correspondences are generated.

3 Sensor fusion

The inertial and vision sensors contained in the sensor unit have complementary properties. Vision in combination with the map gives accurate absolute pose information at a low rate, but experiences problems during moderately fast motions. The IMU provides high rate relative pose information regardless of the motion speed, but becomes inaccurate after a short period of time. By fusing information from both sources it is possible to obtain robust camera pose estimates.

Combing inertial and vision sensors is possible in several ways. For instance, vision based methods might be extended by using pose predictions from the IMU. These pose predictions can be used to determine where in the image the features are to be expected. Once detected, the features can be used to calculate the pose and this pose is then used as a starting point for the next pose prediction by the IMU. Alternatively, the IMU can be considered to be the main sensor, which is quite common in the navigation industry. In that case, vision can be used for error correction, similar to how radio beacons or the *global positioning system* (GPS) are used to correct the drift in an *inertial navigation system* (INS).

Although the sensors have different properties, it is from a signal processing perspective not relevant to assign a 'main' sensor and an 'aiding' sensor. Both vision and inertial sensors are equivalent in the sense that they both provide information about the quantity of interest, the camera pose in this application. The objective is to extract as much information as possible from the measurements. More specifically, this amounts to finding the best possible estimate of the filtering *probability density function* (pdf) $p(x_t|y_{1:t})$, where $y_{1:t} \triangleq \{y_1, \ldots, y_t\}$. The topic of this section is to provide a solid framework for computing approximations of this type. First, a rather general introduction to this framework is given in Section 3.1. The rest of this section is devoted to explaining how this framework can be applied to handle the present application. The models are introduced in Section 3.2 and the fusion algorithm is discussed in Section 3.3.

3.1 Theoretical framework

The objective in sensor fusion is to recursively in time estimate the state in the dynamic model,

$$x_{t+1} = f_t(x_t, u_t, v_t), \tag{4a}$$

$$y_t = h_t(x_t, u_t, e_t), \tag{4b}$$

where $x_t \in \mathbb{R}^{n_x}$ denotes the state, $y_t \in \mathbb{R}^{n_y}$ denote the measurements from a set of sensors, v_t and e_t denote the stochastic process and measurement noise, respectively. The process model equations, describing the evolution of the states (pose etc.) over time are denoted by $f : \mathbb{R}^{n_x} \times \mathbb{R}^{n_v} \times \mathbb{R}^{n_u} \to \mathbb{R}^{n_x}$. Furthermore, the measurement model is given by $h : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_e} \to \mathbb{R}^{n_y}$, describing how the measurements from the IMU and the camera relate to the state. The goal is to infer all the information from the measurements y_t onto the state x_t. The way of doing this is to compute the filtering pdf $p(x_t|y_{1:t})$. The filtering pdf contains everything there is to know about the state at time t, given the information in all the past measurements $y_{1:t}$. Once an approximation of $p(x_t|y_{1:t})$ is available it can be used to form many different (point) estimates, including maximum likelihood estimates, confidence intervals and the most common conditional expectation estimate

$$\hat{x}_t = E(x_t|y_{1:t}). \tag{5}$$

The key element in solving the nonlinear state estimation problem in real-time is the propagation of $p(x_t|y_{1:t})$

over time. It is well known (see e.g., Jazwinski 1970) that a recursive solution can be obtained by applying Bayes' theorem, introducing model (4) in the iterations,

$$p(x_t|y_{1:t}) = \frac{p(y_t|x_t)p(x_t|y_{1:t-1})}{\int p(y_t|x_t)p(x_t|y_{1:t-1})dx_t}, \tag{6a}$$

$$p(x_{t+1}|y_{1:t}) = \int p(x_{t+1}|x_t)p(x_t|y_{1:t})dx_t. \tag{6b}$$

Hence, the quality of the solution is inherently coupled to the models and hence good models are imperative. It is worth noticing that (6a) and (6b) are often referred to as measurement update and time update, respectively. The sensor fusion problem has now been reduced to propagating (6) over time as new measurements arrive. The problem is that the multidimensional integrals present in (6) lack analytical solutions in all but a few special cases. The most common special case is when (4) is restricted to be a linear dynamic system, subject to additive Gaussian noise. Then all the involved densities will be Gaussian, implying that it is sufficient to propagate the mean and covariance. The recursions updating these are of course given by the Kalman filter (Kalman 1960).

However, in most cases there does not exist a closed form solution for (6), forcing the use of approximations of some sort. The literature is full of different ideas on how to perform these approximations. The most common being the EKF (Smith et al 1962; Schmidt 1966) where the model is linearized and the standard Kalman filter equations are used for this linearized model. A conceptually more appealing approximation is provided by the PF (Gordon et al 1993; Isard and Blake 1998; Kitagawa 1996) which retains the model and approximates (6). Other popular approximations for the nonlinear state estimation problem are provided for example by the UKF (Julier and Uhlmann 2004) and the point-mass filter (Bucy and Senne 1971; Bergman 1999). For a more complete account of the nonlinear state estimation problem, see e.g., Schön (2006).

3.2 Models

The probability density functions $p(x_{t+1}|x_t)$ and $p(y_t|x_t)$ are the key elements in the filter iterations (6). They are usually implicitly specified by the process model (4a) and the measurement model (4b). For most applications the model formulation given in (4) is too general. It is often sufficient to assume that the noise enters additively, according to

$$x_{t+1} = f_t(x_t) + v_t, \tag{7a}$$

$$y_t = h_t(x_t) + e_t. \tag{7b}$$

The fact that the noise is additive in (7) allows for explicit expressions for $p(x_{t+1}|x_t)$ and $p(y_t|x_t)$, according to

$$p(x_{t+1}|x_t) = p_{v_t}(x_{t+1} - f_t(x_t)), \tag{8a}$$

$$p(y_t|x_t) = p_{e_t}(y_t - h_t(x_t)), \tag{8b}$$

where $p_{v_t}(\cdot)$ and $p_{e_t}(\cdot)$ denote the pdf's for the noise v_t and e_t, respectively. Note that the input signal u_t has been dispensed with, since it does not exist in the present application. The rest of this section will discuss the model used in the current application.

First of all, the state vector has to include the position and the orientation, since they are the quantities of interest. However, in order to be able to use the IMU and provide predictions the state vector should also include their time derivatives, as well as sensor biases. The state vector is chosen to be

$$x_t = \left(\boldsymbol{b}_t^e \ \dot{\boldsymbol{b}}_t^e \ \ddot{\boldsymbol{b}}_t^e \ q_t^{be} \ \boldsymbol{\omega}_{eb,t}^b \ \boldsymbol{\delta}_{\omega,t}^b \ \boldsymbol{\delta}_{a,t}^b\right)^T. \tag{9}$$

That is, the state vector consists of position of the IMU (the body coordinate system) expressed in the earth system $\boldsymbol{b}^e$, its velocity $\dot{\boldsymbol{b}}^e$ and acceleration $\ddot{\boldsymbol{b}}^e$, the orientation of the body with respect to the earth system q^{be}, its angular velocity $\boldsymbol{\omega}_{eb}^b$, the gyroscope bias $\boldsymbol{\delta}_{\omega}^b$ and the accelerometer bias $\boldsymbol{\delta}_{a}^b$. All quantities are three dimensional vectors, except for the orientation which is described using a four dimensional unit quaternion q^{be}, resulting in a total state dimension of 22. Parameterization of a three dimensional orientation is in fact rather involved, see e.g., Shuster (1993) for a good account of several of the existing alternatives. The reason for using unit quaternions is that they offer a nonsingular parameterization with a rather simple dynamics. Using (9) as state vector, the process model is given by

$$\boldsymbol{b}_{t+1}^e = \boldsymbol{b}_t^e + T\dot{\boldsymbol{b}}_t^e + \tfrac{T^2}{2}\ddot{\boldsymbol{b}}_t^e, \tag{10a}$$

$$\dot{\boldsymbol{b}}_{t+1}^e = \dot{\boldsymbol{b}}_t^e + T\ddot{\boldsymbol{b}}_t^e, \tag{10b}$$

$$\ddot{\boldsymbol{b}}_{t+1}^e = \ddot{\boldsymbol{b}}_t^e + \boldsymbol{v}_{\ddot{b},t}^e, \tag{10c}$$

$$q_{t+1}^{be} = \exp(-\tfrac{T}{2}\boldsymbol{\omega}_{eb,t}^b) \odot q_t^{be}, \tag{10d}$$

$$\boldsymbol{\omega}_{eb,t+1}^b = \boldsymbol{\omega}_{eb,t}^b + \boldsymbol{v}_{\omega,t}^b, \tag{10e}$$

$$\boldsymbol{\delta}_{\omega,t+1}^b = \boldsymbol{\delta}_{\omega,t}^b + \boldsymbol{v}_{\delta_\omega,t}^b, \tag{10f}$$

$$\boldsymbol{\delta}_{a,t+1}^b = \boldsymbol{\delta}_{a,t}^b + \boldsymbol{v}_{\delta_a,t}^b, \tag{10g}$$

where the quaternion multiplication and exponential are defined according to

$$\begin{pmatrix} p_0 \\ \boldsymbol{p} \end{pmatrix} \odot \begin{pmatrix} q_0 \\ \boldsymbol{q} \end{pmatrix} \triangleq \begin{pmatrix} p_0 q_0 - \boldsymbol{p}\cdot\boldsymbol{q} \\ p_0\boldsymbol{q} + q_0\boldsymbol{p} + \boldsymbol{p}\times\boldsymbol{q} \end{pmatrix}, \tag{11a}$$

$$\exp(\boldsymbol{v}) \triangleq \begin{pmatrix} \cos\|\boldsymbol{v}\| \\ \frac{\boldsymbol{v}}{\|\boldsymbol{v}\|}\sin\|\boldsymbol{v}\| \end{pmatrix}. \tag{11b}$$

A standard constant acceleration model (10a)– (10c) has been used to model the position, velocity and acceleration. Furthermore, the quaternion dynamics is standard, see e.g., Shuster (1993). Finally, the angular velocity and

the bias terms are simply modeled as random walks, since there is no systematic knowledge available about these terms.

There is more than one sensor type available, implying that several measurement models are required. They have already been introduced in Section 2, but for convenience they are all collected here,

$$\boldsymbol{y}_{a,t} = R_t^{be}(\ddot{\boldsymbol{b}}_t^e - \boldsymbol{g}^e) + \boldsymbol{\delta}_{a,t}^b + \boldsymbol{e}_{a,t}^b, \tag{12a}$$

$$\boldsymbol{y}_{\omega,t} = \boldsymbol{\omega}_{eb,t}^b + \boldsymbol{\delta}_{\omega,t}^b + \boldsymbol{e}_{\omega,t}^b, \tag{12b}$$

$$\boldsymbol{y}_{c,t} = \begin{pmatrix} -fI_2 & \boldsymbol{z}_t^i \end{pmatrix} R^{cb}(R_t^{be}(\boldsymbol{z}_t^e - \boldsymbol{b}_t^e) - \boldsymbol{c}_t^b) + \boldsymbol{e}_{c,t}. \tag{12c}$$

Note that the rotation matrix R_t^{be} is constructed from q_t^{be} (Kuipers 1999). The transformation from body to camera coordinate system is included in (12c), compared to (3b).

3.3 Fusion Algorithm

The nonlinear estimation framework discussed in Section 3.1 suggests Algorithm 1 to fuse the multi-rate information from the inertial and vision sensors. The algorithm uses the models (10) and (12) to perform the time and measurement update steps given in (6). Note that Algorithm 1 is generic in the sense that we have not specified which state estimation algorithm is used. Our implementation, which runs in real-time with 100 Hz inertial measurements and frame rates up to 25 Hz, uses the EKF to compute the estimates, implying that all involved pdf's are approximated by Gaussian densities. An UKF implementation was found to give similar accuracy at the cost of a higher computational burden (Pieper 2007). This confirms the results from Armesto et al (2007).

Algorithm 1 Recursive camera pose calculation

1. Perform an initialization and set initial state estimate and covariance.

   $x_0 \sim p(x_o)$

2. Time update. Calculate $p(x_t|y_{1:t-1})$ by propagating $p(x_{t-1}|y_{1:t-1})$ through the process model (10).
3. Accelerometer and gyroscope measurement update using model (12a) and (12b).

   $x_t \sim p(x_t|y_{1:t})$

4. If there is a new image from the camera,
   (a) Predict feature positions from the scene model using $\hat{x}_t = E(x_t|y_{1:t})$.
   (b) Detect the features in the image.
   (c) Measurement update with the found point correspondences using model (12c).

   $x_t \sim p(x_t|y_{1:t})$

5. Set $t := t + 1$ and iterate from step 2.

When the sensor unit is static during initialization, the IMU provides partial or full (using magnetometers) orientation estimates. This information can be used to constrain the search space when initializing from vision.

The high frequency inertial measurement updates in Algorithm 1 provide a rather accurate state estimate when a new image is acquired. This implies that the feature positions can be predicted with an improved accuracy, which in turn makes it possible to use a guided search in the image using reduced search regions. The algorithm can calculate the expected covariance of a measurement. This can be the basis for a temporal outlier removal as a complement to the spatial outlier removal provided by RANSAC methods (Fischler and Bolles 1981). Alternatively it can be used to predict the amount of new information that a certain feature can contribute, which might be useful for task scheduling when the computational resources are limited (Davison 2005).

The camera pose is estimated implicitly by Algorithm 1 rather than trying to determine it explicitly by inverting the measurement equations. Hence, when sufficient motion is present, the system is able to continue tracking with a very low number of features and maintain full observability using temporal triangulation.

The information from the IMU makes Algorithm 1 robust for temporary absence of vision. Without vision measurements the estimates will eventually drift away. However, short periods without vision, for instance, due to motion blur, obstruction of the camera or an unmodeled scene, can be handled without problems.

Finally, Algorithm 1 is rather flexible. It can be rather straightforwardly extended to include other information sources. For instance, a GPS might be added to aid with outdoor applications.

4 Implementation considerations

When implementing Algorithm 1, several practical issues have to be solved. These turn out to be critical for a successful system, motivating their treatment in this section.

4.1 Metric scale

As mentioned in Section 2.3, vision-only methods suffer from a scale ambiguity, since projections, unit-less measurements, are used. Once the scale of the scene model is defined, camera pose can be determined explicitly using three or more correspondences in combination with a calibrated camera. However, changing the scale of a scene model will give scaled, but indistinguishable poses. Hence, for vision-only applications scene models can have

an arbitrary scale; a standard choice is to define the unit length to be the distance between the first two cameras.

For the inertial-vision combination, the scale is relevant. Sensor fusion utilizes position information both from the camera and the IMU, which implies that these quantities must have identical units. Scale is also important when assumptions are made about the motions of the camera, for instance the type and parameters of a motion model (Davison et al 2007).

Introducing a metric scale into the scene model solves this issue. An existing scene model with arbitrary scale can be converted by comparing it with a *Computer Aided Design* (CAD) model or measuring an object with known dimension. An interesting solution might be to include metric information, for instance using accelerometers, in the algorithms for building the scene models. However, this is still an open question.

4.2 Vertical alignment

Accelerometers cannot distinguish accelerations of the body from gravity, as previously discussed in Section 2.2. To separate the contributions in the measurement, the gravity vector can be rotated from the earth coordinate system to the body frame and then subtracted. Hence, the scene model should be vertically aligned, or equivalently the gravity vector should be known in the scene model. Typically, this is not the case.

The performance of the system is extremely sensitive to this alignment, since gravity is typically an order of magnitude larger than normal body accelerations. For example, a misalignment of 1° introduces an artificial acceleration of $0.17\ \mathrm{m/s^2}$ which gives rise to a systematic position drift of 8.5 cm when integrated over 1 s. Hence, even for small errors a systematic drift is introduced which causes the system to lose track without continuous corrections from correspondences. In this case the drift followed by a correction gives rise to a sawtooth pattern in the estimates, which deteriorates performance and will be visible as 'jitter'.

The gravity vector can be determined by averaging the accelerometer readings over some time, while the camera is stationary in a known pose. However, a preferable method is to record accelerometer measurements while scanning the scene and include this data in the model building procedure to align the scene model vertically.

4.3 Sensor pose calibration

The camera and the IMU both deliver measurements which are resolved in the camera and the body coordinate system, respectively. Typically, these do not coincide, since the sensors are physically translated and rotated with respect to each other. This rigid transformation should be taken into account while fusing the measurements.

The problem of determining the relative position and orientation is a well studied problem in robotics where it is known as hand-eye calibration, see e.g., Strobl and Hirzinger (2006) for an introduction to this topic. However, most methods do not apply directly since the IMU does not provide an absolute position reference. Absolute orientation information is available since the accelerometers measure only gravity when the sensor unit is stationary.

The orientation part of the calibration is determined using a slight modification of standard camera calibration procedures (Zhang 2000), where the calibration pattern is placed on a horizontal surface and accelerometer readings are taken in the various camera poses. The camera poses are determined in the camera calibration procedure, from which the vertical directions in the camera frame can be determined. The combination of these and the vertical directions in the body frame measured by the accelerometers allows for calculation of the rotation between the frames (Horn 1987; Lobo and Dias 2007). This method requires accurate positioning of the calibration pattern. As floors and desks in buildings are in practice better horizontally aligned than the walls are vertically aligned, it is recommended to use horizontal surfaces.

The translational part of the calibration is harder to estimate and a solid calibration method which does not require special hardware is an open issue. The translation should also be available from technical drawings of the sensor unit and a rough guess using a ruler gives a quite decent result in practice. However, with increasing angular velocity this parameter becomes more dominant and an accurate calibration is necessary.

4.4 Time synchronization

It is very important to know exactly when the different measurements are taken. Multiple sensors usually have multiple clocks and these have to be synchronized. This can be achieved for instance by starting them simultaneously. However, clocks tend to diverge after a while, which will introduce problems during long term operation. Hardware synchronization, i.e., one central clock is used to trigger the other sensors, solves this problem and this procedure has been applied in the sensor unit described in Section 2.

4.5 Filter tuning

The process and measurement models described in Section 3 have a number of stochastic components which are used to tune the filter. The settings used in the present

setup are given in Table 1. The measurement noise typically depends on the sensors and should be experimentally determined. For the accelerometers and gyroscopes a measurement of a few seconds with a static pose was recorded to calculate an accurate noise covariance. Alternatively, the specification by the manufacturer can be used.

The noise acting on the vision measurements is harder to determine. The algorithms return a point estimate for the obtained matches, but typically there is no stochastic information available. The accuracy for each match is highly individual and can vary a lot depending on e.g., lighting conditions, local texture, viewing angle, distance and motion blur. These individual characteristics cannot be captured by a common noise setting. Hence, it would be beneficial to include accuracy estimation in the image processing algorithms. Although attempts are being made to solve this open issue, see e.g., Skoglund and Felsberg (2007), the current implementation uses a predefined noise covariance.

The process model currently used is a random walk in acceleration and angular velocity. This model is not so informative but is very general and is useful for tracking uncontrolled motions such as those generated by a human. The motion model is to be considered as a separate source of information, apart from the sensors. Hence, when more information is available in a certain application, for instance in the form of control signals, these should be included in the model to improve the filter performance. The covariances in the process model can be seen as tuning knobs, controlling the relative importance of the measurements and the process model and as such they are important parameters for stable tracking.

Valid models and parameters are imperative to obtain good estimates. The innovations, defined as the difference between a measurement and its expected value,

$$e_t = y_t - \hat{y}_t, \tag{13}$$

can be used to asses whether the models are correctly tuned. Under the model assumptions, the innovations should be normally distributed and the squared normalized innovations $e_t^T S_t^{-1} e_t$, where S_t is the predicted covariance of the measurement, should have a χ^2 distribution. It is highly recommendable to monitor these performance indicators, especially during testing, but also during normal operation.

5 Experiments

This section is concerned with an experiment where Algorithm 1 with an EKF is used to fuse the measurements from the sensor unit in order to compute estimates of its position and orientation. The experimental setup is discussed in Section 5.1 and the performance of the proposed inertial-vision combination provided by the sensor unit is assessed in Section 5.2.

5.1 Setup

The sensor unit is mounted onto a high precision 6 degrees of freedom (DoF) ABB IRB1440 industrial robot, see Figure 3. The reason for this is that the robot will allow us to make repeatable 6 DoF motions and it will provide the true position and orientation. The robot has an absolute accuracy of 2 mm and a repeatability of 0.2 mm. This enables systematic and rather objective performance evaluation of various algorithms, based on absolute pose errors instead of the commonly used feature reprojection errors. The sensor unit provides 100 Hz inertial measurements synchronized with 12.5 Hz images. The complete specification is listed in Table 1. The scene

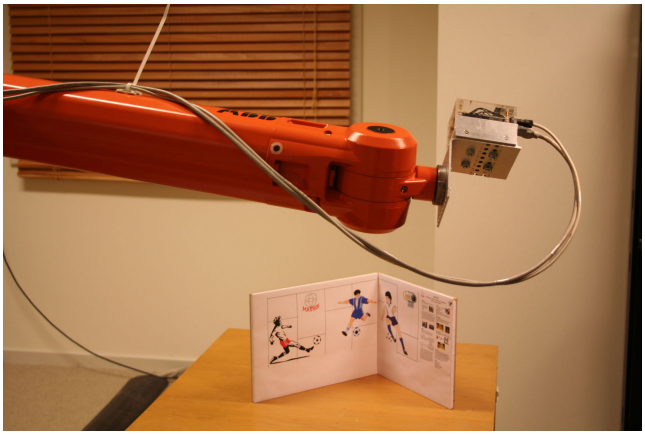

Fig. 3 The camera and the IMU are mounted onto an industrial robot. The *background* shows the scene that has been used in the experiments.

Table 1 Specifications for the sensor unit and the parameter values used for in the filter tuning. Note that the noise parameters specify the standard deviation.

IMU	
gyroscope range	±20.9 rad/s
gyroscope bandwidth	40 Hz
accelerometer range	±17 m/s^2
accelerometer bandwidth	30 Hz
sample rate	100 Hz
Camera	
selected resolution	320 × 240 pixel
pixel size	7.4 × 7.4 µm/pixel
focal length	3.2 mm
sample rate	12.5 Hz
Filter settings	
gyroscope measurement noise	0.01 rad/s
accelerometer measurement noise	0.13 m/s^2
2D feature measurement noise	0.1 pixel
3D feature measurement noise	1 mm
angular velocity process noise	0.03 rad/s
acceleration process noise	0.1 m/s^2
gyroscope bias process noise	0.5 mrad/s
accelerometer bias process noise	0.5 mm/s^2

used for the experiments consists of two orthogonal planar surfaces as shown in Figure 3. Because of the simple geometry, the scene model could be constructed from a textured CAD model. Its coordinate system is such that the x-axis points upward and that the y and z-axis span the horizontal plane. Although the scene was carefully positioned, it had to be calibrated w.r.t. gravity as described in Section 4.2. It should be emphasized that the scene has been kept simple for experimentation purposes only. The system itself can handle very general scenes and these are modeled using the methods described in Koeser et al (2007).

With the setup several trajectories have been tested. In this paper, an eight-shaped trajectory, shown in Figure 4, will be discussed in detail. The sensor unit traverses this 2.6 m eight-shaped trajectory in 5.4 s, keeping the scene in view at all times. The motion contains accelerations up to 4 m/s^2 and angular velocities up to 1 rad/s. Hence, the motion is quite aggressive and all six degrees of freedom are exited. As the displacement between images is limited to 15 pixels it is still possible to use vision-only tracking, which allows for a comparison between tracking with and without an IMU.

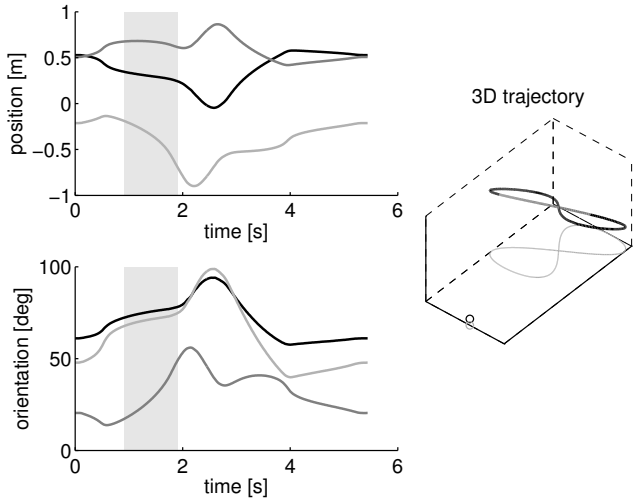

Fig. 4 The eight-shaped trajectory undertaken by the sensor unit. The *gray shaded parts* mark the interval where vision is deactivated. The *circle* indicates the origin of the scene model.

The experiment starts with a synchronization motion, which is used to synchronize the ground truth data from the industrial robot with the estimates from the system. Time synchronization is relevant, since a small time offset between the signals will result in a significant error. After the synchronization, the eight-shaped trajectory (see Figure 4) is repeated several times, utilizing the accurate and repeatable motion provided by the industrial robot.

5.2 Results

The experimental setup described in the previous section is used to study several aspects of the combination of vision and inertial sensors. The quality of the camera pose estimates is investigated by comparing them to the ground truth data. Furthermore, the increased robustness of the system is illustrated by disabling the camera for 1 s during the second pass of the eight-shaped trajectory. Additionally, the feature predictions are shown to benefit from the inertial measurements. The findings will be discussed in the following paragraphs.

By comparing the estimates from the filter to the ground truth the tracking errors are determined. Examples of position and orientation errors (z, roll) are shown in Figure 5. The other positions (x, y) and orientations (yaw, pitch) exhibit similar behavior. The absolute accuracy (with vision available) is below 2 cm for position and below 1° for orientation. These values turn out to be typical for the performance of the system in the setup described above. Furthermore, the accuracy of the IMU is not affected by the speed of motion, resulting in a tracking accuracy which is rather independent of velocity, as

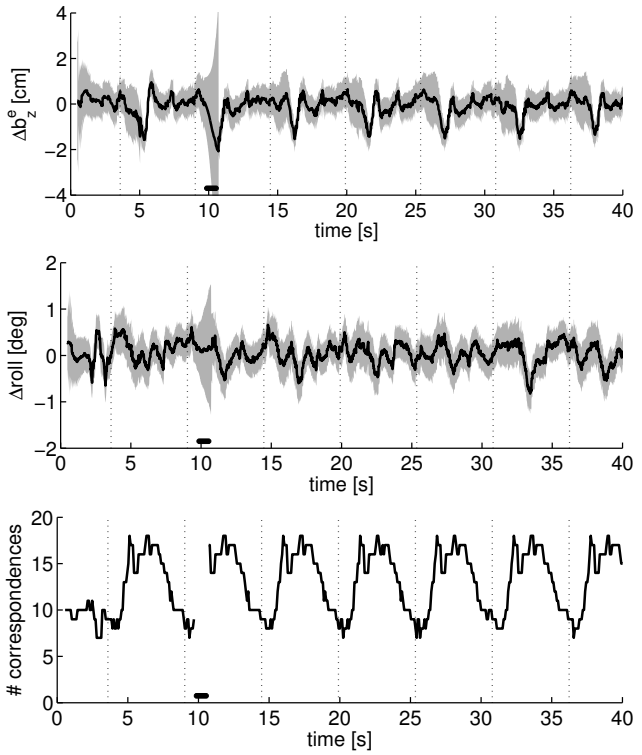

Fig. 5 Tracking error during multiple passes of the eight-shaped trajectory. The *black line* shows the position (z) and orientation (roll) errors, as well as the number of correspondences that were used. The *gray band* illustrates the 99% confidence intervals. Note that vision is deactivated from 9.7 s to 10.7 s. The *vertical dotted lines* mark the repetition of the motion.

illustrated by Figure 6 which shows the tracking error of the eight-shaped trajectory executed at various speeds. Other experiments, not described here, show similar performance for various trajectories.

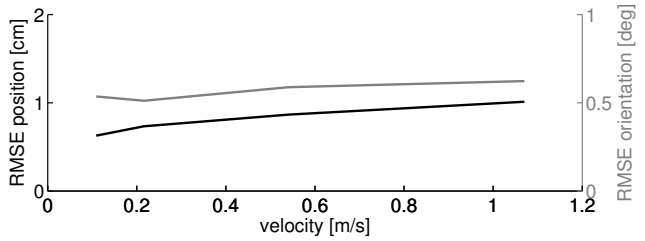

Fig. 6 Tracking error for several experiments executing the eight-shaped trajectory at different speeds.

A proper treatment of the implementation considerations as discussed in Section 4 is necessary in order to obtain good performance. Still, calibration errors and slight misalignments as well as scene model errors and other unmodeled effects are causes for non-white noise, which can deteriorate the performance. However, with the assumptions and models used, the system is shown to estimate the camera pose quite accurately using rather low-rate vision measurements. The estimated camera poses result in good and stable augmentation.

The system tracks the camera during the entire experiment, including the period where vision is deactivated. The motion during this period, indicated using gray segments in Figure 4, is actually quite significant. Vision-only tracking has no chance of dealing with such a gap and loses track. Indeed, such an extensive period where vision is deactivated is a little artificial. However, vision might be unavailable or corrupted, due to fast rotations, high velocity, motion blur, or simply too few visible features. These difficult, but commonly occurring, situations can be dealt with by using an IMU as well, clearly illustrating the benefits of having an IMU in the system. In this way, robust real-time tracking in realistic environments is made possible.

The measurements from the IMU will also result in better predictions of the feature positions in the acquired image. This effect is clearly illustrated in Figure 7, which provides a histogram of the feature prediction errors. The figure shows that the feature prediction errors are smaller and more concentrated in case the IMU measurement updates are used. This improvement is most significant when the camera is moving fast or at lower frame rates. At lower speeds, the vision based feature predictions will improve and the histograms will become more similar.

The improved feature predictions facilitate the use of smaller search regions to find the features. This implies that using an IMU more features can be detected, given a certain processing power. On the other hand, the improved feature predictions indicate that the IMU handles the fast motion and that the absolution pose information which vision provides is required at a reduced rate.

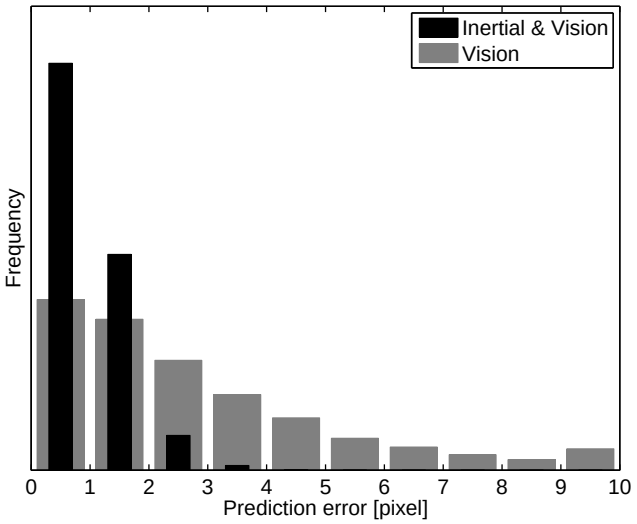

Fig. 7 Histogram of the prediction errors for the feature positions. The feature predictions are calculated using the latest vision pose and the most recent inertial pose, respectively.

6 Conclusion

Based on a framework for nonlinear state estimation, a system has been developed to obtain real-time camera pose estimates by fusing 100 Hz inertial measurements and 12.5 Hz vision measurements using an EKF. Experiments where an industrial robot is used to move the sensor unit show that this setup is able to track the camera pose with an absolute accuracy of 2 cm and 1°. The addition of an IMU yields a robust system which can handle periods with uninformative or no vision data and it reduces the need for high frequency vision updates.
